Abstract

Objective: Healthcare system distrust (HCSD) has been linked to poor breast cancer outcomes. Previous HCSD analyses have focused on Black-White disparities; however, focusing only on race ignores the complex set of factors that form identity. We quantified the contributions of race and sexual minority (SM) identity to HCSD among US women who had received breast cancer screening.

Methods: This cross-sectional study used intersectionality decomposition methods to assess the degree to which racial and SM identity contributed to disparate responses to the validated 9-item HCSD Scale. The sample included online survey participants identifying as a Black or White woman living in the US, with a self-reported abnormal breast cancer screening result in the past 24 months and/or breast cancer diagnosis since 2011.

Results: Of 649 participants, 49.4% of Black SM women ($n = 85$) were in the highest HCSD tertile, followed by 37.4% of White SM women ($n = 123$), 24.4% of Black heterosexual women ($n = 156$), and 19% of White heterosexual women. Controlling for age, 72% of the disparity in HCSD between Black SM women and White heterosexual women was due to SM status, 23% was due to racial identity, and 3% was due to both racial and SM identity.

Conclusions: SM identity emerged as the largest driver of HCSD disparities; however, the combined racial and SM disparity persisted. Excluding sexual identity in HCSD studies may miss an important contributor. Interventions designed to increase the HCS's trustworthiness at the provider and system levels should address both racism and homophobia.

1 | BACKGROUND

Healthcare system distrust (HCSD) is a persistent challenge in breast cancer care in the United States.¹ It has been linked to poor outcomes across the breast cancer continuum¹ from screening, genetic testing, and counseling²⁻⁴ to treatment^{5,6} and survivorship.^{6,7} While HCSD is often thought of as a property of individuals, warranted distrust reflects properties of institutions that reinforce racism, homophobia and other forms of discrimination that make those institutions untrustworthy.⁸ Thus, understanding the characteristics of those at risk of experiencing HCSD is critical to cancer care.

Previous studies on HCSD differences focus on race,^{8,9} and find that (healthcare system) HCS untrustworthiness is a well-established barrier to care for Blacks compared to Whites¹⁰⁻¹³; however, focusing only on racial minority identity ignores the complex set of factors that form identity. For example, previous studies suggest that HCSD among sexual minorities is high,^{9,14-16} and is often associated with fear of stigmatization due to sexual minority (SM) identity. Racial/ethnic minorities who are also sexual minorities may experience dual marginalization within healthcare due to being at the intersection of racism and homophobia,⁹ and may be at even greater risk of HCSD than those identifying as either a racial minority or SM.

Examination of the combined contributions of race and sexual identity to beliefs in the HCS's trustworthiness is largely unexamined overall.^{1,14} The few studies on mistrust that have focused on both race and sexual identity^{9,14-16} have not been in breast cancer, where these identities clearly pattern care. Being Black is associated with diagnosis at later stages of breast cancer, longer time between mammograms, and lack of timely follow-up after abnormal mammograms¹⁷⁻¹⁹ than Whites, even among those who are insured.²⁰ Being an SM is associated with low rates of screening, less timely screening,²¹⁻²⁵ and delays after an abnormal screening.²⁶ However, studies at the intersection of racial and sexual identity show a more complex trend: While a lower percentage of Black SM women use mammography than White SM women, White bisexual women have lower odds of mammography than White heterosexual women while Black bisexual women have higher odds of mammography than Black SM women.²⁷ Disparities in the receipt of care by racial and SM identity may be attributed to the experiences of discrimination that racial or SM groups experience that signal untrustworthiness of the HCS. Our understanding of how identity relates to HCSD ratings in breast cancer is a gap that must be filled in order to address the roots of care disparities.

Both race and sexual identity are markers of differential treatment in society, such that the contributions of each reflect complex historical processes for which they are a proxy measure.^{28,29} New methods now enable us to assess the extent to which disparities in health outcomes and exposures related to various parts of identity: race, sexual identity, or the intersection of both race and sexual identity.^{30,31} Applying these new methods, this analysis sought to answer the question: To what extent does being a racial or SM

2 | METHODS

2.1 | Sample

From June 2018 to October 2019, we recruited participants through targeted emails to specific breast cancer interest groups (i.e., Susan Love Research Army, the Pride Study, the Pride Study, the National Lesbian, Gay, Bisexual, Transgender (LGBT) Cancer Network, Living Beyond Breast Cancer), Facebook posts, social media promotion through breast cancer advocates (Ericka Hart), and via personal referrals. Our community partner, the National Organization of Black Lesbians on Aging (ZAMI NOBLA), boosted participation by Black SM women through recruitment at health fairs and churches affirming same gender-loving persons. Participants provided online informed consent prior to accessing the online survey questions.

An initial 2,798 individuals completed the survey's screening questions to determine eligibility, of which 852 were eligible for the survey based on screening questions. Eligibility for the survey included being aged 35 or older, assigned female at birth, currently identifying as a Black or White woman and with a self-reported abnormal clinical breast exam, mammogram, breast magnetic resonance imaging (MRI), or breast ultrasound result in the past 24 months and/or diagnosed with breast cancer since 2011. Of all those eligible, 851 completed the survey yielding a 99.8% completion rate. Of the 851 women who completed the survey, 123 were excluded from this analysis for the following reasons: 94 women identified as a race other than Black or White and/or did not identify their sexual orientation; and 30 women were eligible based on responses to their screening question but were later deemed ineligible based on survey questions about breast cancer history. Among the 728 women remaining, 79 women did not provide complete information to calculate the HCSD variable. The final analytic sample was 649.

Survey items included self-reported demographics, behavioral questions about delays in care-seeking following breast cancer diagnosis or abnormal screening (results reported in²⁶), and structural and psychosocial barriers to or facilitators of seeking care. The study was approved by the Johns Hopkins Bloomberg School of Public Health Institutional Review Board (protocol #00007908), and the study conforms to standards outlined in the Declaration of Helsinki and the US Federal Policy for the Protection of Human Subjects. Further details on survey development and recruitment are previously published.²⁶

2.2 | Measures

Intersectional identity: Race and SM status were self-reported. Patients not identifying as Black or White were excluded from analysis. Ethnicity was asked as a separate question. Regardless of ethnicity, all individuals who identified as Black were coded as Black. SM women were classified as those who self-identified as lesbian,

contribute to HCSD among those seeking follow-up care after breast cancer screening?

gay, queer, bisexual, or same-gender loving, and were coded as SM. Women who identified as Straight/Heterosexual were coded as

nonsexual minority (NSM). The sample was analyzed across four intersectional groups: White NSM, White SM, Black NSM, and Black SM women.

Sample characteristics: Participants self-reported current insurance and type of insurance. Experiences of discrimination were measured by the 13-item Intersectional Discrimination Index–Major (InDI-M) scale,³² with higher values representing greater discrimination during experiences with healthcare, housing, employment or interpersonal relationships (Cronbach's $\alpha = 0.81$ in this sample). Charlson comorbidity score³³ was included as a measure of the health of the patient based on the patient's self-reported number of diagnosed comorbid conditions.

Healthcare system trustworthiness: Participants completed the validated 9-item Health Care System Distrust scale^{34,35} which measures subdomains of: *values* distrust, which reflects the fidelity, honesty, and belief that the healthcare system will act in the best interest of the patient, and *competence* distrust, which reflects the perceptions of the healthcare system's ability and knowledge to perform in the expected way.³⁶ Items focus on discrimination by race and insurance, beliefs about unethical experimentation by the HCS, and that the HCS prioritizes making money over healing patients. Item responses were on a 5-point agreement scale (1 = strongly disagree, 5 = strongly agree), with summary score ranges from 9 to 45. The measure has high internal consistency in the current sample, with a Cronbach's $\alpha = 0.88$ for the overall sample, with scores of 0.86 for White NSM, 0.83 for White SM, 0.87 for Black NSM, and 0.91 for Black SM women subgroups.

2.3 | Analysis

We calculated descriptive statistics on the overall sample, and each of four identity-based subsamples: White NSM women, White SM women, Black NSM women, and Black SM women. For continuous variables mean values across groups were compared with one-way ANOVA. For categorical variables, values across groups were compared with Pearson's chi-squared tests.

To complete the intersectional analysis, we used decomposition methods developed by Jackson and colleagues^{30,31} to separate out how much race and SM status contributed to HCSD. This method uses a linear regression model to calculate four different metrics¹: the joint disparity, or the overall difference between someone who is Black and SM and someone who is White and not an SM²; the referent race disparity, in our case, the contribution that being Black makes to HCSD³; the referent sexual identity disparity, in our case, the contribution that SM status makes to HCSD; and the⁴ excess intersectional disparity, or the additional contribution that being both Black and SM makes to HCSD, above and beyond the sum of the racial and sexual identity disparity. We calculated the percentage of disparity attributable to specific identities as the percentage of the joint disparity explained by each of the

Our linear regression model adjusted only for age due to differential risk for breast cancer by age and that Black women are more likely to have a breast cancer diagnosis at a younger age than White women, and because differences in comorbidities were predicted by age. The decomposition method used is rooted in a causal inference perspective, meaning that additional sociodemographic covariates such as insurance, education, or income would need to be modeled as mediators between intersectional identity and HCSD. Even if we had modeled these factors as mediators, their contributions would still be driven by the intersectional identity exposure, which absorbs their influence. Thus, ultimately, we opted not to include these variables in the decomposition analysis. We also did not include stigma or discrimination because the distrust measure already includes items about discrimination, raising issues of endogeneity. We report these variables only to characterize each subsample.

3 | RESULTS

Six hundred and forty-nine women responded to the HCSD question and were classified as either Black or White. The mean age across the sample was 55, and the majority of participants had health insurance (Table 1), though SM women and Black women groups all had lower rates of health insurance than White NSM women. Black and White SM women reported the highest experiences of discrimination, followed by Black NSM and White NSM. Black SM reported highest rates of HCSD untrustworthiness, followed by White SM, Black NSM, and then White NSM.

Figure 1 reports high, medium, and low tertiles of distrust by intersectional identity group. Nearly half (49.4%) of Black SM women were in the highest tertile of HCSD, followed by over one-third (37.4%) of White SM women, and one-quarter (24.4%) of Black NSM women.

Table 2 shows the contributions of each identity to HCSD. The overall difference in HCSD scores between White NSM and Black SM (joint disparity) was 4.67 (−0.14, 9.48). This value could be decomposed into contributions due to Black race (referent race disparity) of 1.12 (−0.14, 2.38), or SM status (referent sexual identity disparity), 3.40 (2.03, 4.77). Above and beyond being a racial or SM, the additional contribution of being both a racial and SM (excess intersectional disparity) was 0.15 (−2.03, 2.33).

The disparity in HCSD, controlling for age, between Black SM women (avg HCSD score = 33.5) and White heterosexual women (avg HCSD score = 28.8) was primarily due to SM status ($(1.12/4.7) \times 100 = 72.3\%$). A smaller proportion of the difference was due to racial identity ($(3.40/4.7) \times 100 = 23.8\%$). An even smaller proportion was due to the intersection between SM status and racial identity ($(0.15/4.7) \times 100 = 3.19\%$).

4 | DISCUSSION

decomposed component (referents and excess intersectional) disparities.

Our results suggest that in a sample of racial and SM women with a history of breast cancer or abnormal breast cancer screening, most of

**FIGURE 1** Distrust tertiles by race and sexual minority status for women receiving breast cancer screening or follow-up care; SM, sexual minority; NSM, nonsexual minority**TABLE 2** Results of healthcare system distrust intersectional decomposition by racial minority and sexual minority identity

	Absolute difference (95% CI)	Interpretation	Percent of joint disparity
Joint disparity	4.67 (−0.14, 9.48)	Difference in average healthcare system distrust score between Black SMW & White NSMW	--
Referent race disparity	1.12 (−0.14, 2.38)	Difference in average health system distrust on the basis of race alone	24%
Referent sexual identity disparity	3.40 (2.03, 4.77)	Difference in average healthcare system distrust score on the basis of sexual minority status alone	72%
Excess intersectional disparity	0.15 (−2.03, 2.33)	Difference in average healthcare system distrust score on the basis of interaction between race and sexual minority identity	3%

the differences in HCSD was due to being an SM or being a racial minority, but no elevation of distrust due to being at the intersection of a racial and SM. The sexual identity referent disparity was the only disparity measure that was statistically significant. This finding combined with the proportion of the joint disparity that is attributed to differences in SM status suggests that SM identity may be driving

neither statistically significant nor a large proportion of the joint disparity, this simply means that the contributions of race and SM identity are additive rather than multiplicative in determining HCSD. The fact that the combined racial and SM disparity exists at all remains important given the possible impact of HCSD on health behaviors and outcomes. These findings suggest that excluding sexual

the difference in HCSD between Black SM women and White heterosexual women. Even though the excess intersectional disparity is

identity in studies of HCSD may miss an important contributor to HCSD that has not been previously captured.

Based on our study findings in a sample of racial and sexual minorities, sexual identity had a greater influence than racial identity on reports of low HCS trustworthiness. These findings may be related to the higher rates of discrimination reported by White SM women than any other group in our sample. There may be several reasons for this finding. White SM women in this study were older and had more comorbidities, which may have resulted in greater need for engagement with the HCS than other groups, thus more opportunities to experience discrimination by the HCS. Another explanation based on previous studies is that Whites may be more likely to perceive discrimination compared with Blacks, despite evidence that they are less likely to experience discrimination.^{37,38} The racial majority privilege that White women experience may be overshadowed by the SM status for White SM women, contributing to high reports of discrimination.

These findings might also be related to disclosure of SM status. Unlike racial minority status, SM status may not be apparent to healthcare provider teams unless the patient discloses it. Healthcare teams may be able to visibly assess when a patient is a racial minority and may be careful to act in trustworthy ways. Providers may even have participated in racial bias training. However, providers may not be able to tell if someone is an SM, and the “white-washing” of lesbian, gay, bisexual, transgender, or queer (LGBTQ) communities³⁹ may mean that providers assume that Black patients are not sexual minorities. An SM patient may feel the need to protect their SM identity if they believe that the HCS cannot be trusted to do right by them otherwise. Therefore, the lack of training and competence (hence, warranted distrust) in serving SM patients may be observed by the patient.

4.1 | Study limitations

While our study advances our understanding of how identity contributes to HCSD, and helps refine in which populations interventions should focus, our results must be considered in light of its limitations. Populations who are most stigmatized or for whom the HCS is least trustworthy may not be engaged in care at all, and our study circumvents that challenge by focusing only on a population that is already engaged in care and has access to healthcare. This enables us to further isolate the causal influences of race and sexual identity. Our study focused on a sample of women over age 35 seeking breast cancer care and may not represent the full spectrum of SM women or age groups; however, rates of breast cancer screening in the United States are high and rising, thus targeting a breast cancer-related sample would be expected to include a broad sample. Additionally, perspectives of HCS trustworthiness by those identifying both as racial and sexual minorities in cancer care is lacking, so our study is an anchor contribution in an understudied area.

4.2 | Clinical implications

previous qualitative work with Black SM women one breast cancer patient expressed frustration that there was a breast cancer support group specifically geared toward male but not female partners of breast cancer survivors.⁴⁰ Altogether, these results and examples suggest an increased need for interventions at the provider and healthcare system levels in cancer screening and care to regain trust among racial and SM patients.

5 | CONCLUSION

HCS untrustworthiness has been linked to poor outcomes across the breast cancer continuum (1) and our analysis adds the importance of the role of intersectional identity in HCSD distrust. While previous studies suggested high rates of HCSD for Black racial/ethnic minorities, our analysis suggests even higher HCSD by SM status which supercedes that associated with racial identity alone. Nonetheless, greater attribution of HCSD disparities to sexual identity than racial identity does not minimize the race difference of HCSD, but rather, shows that for those at the intersection of race and SM, discrimination due to SM status may be a greater concern to patients. To ward eliminating breast cancer disparities, institutions within the healthcare system, from insurance to clinics to provider-patient dyads, need multilevel interventions to address homophobia and racism that lead to HCS untrustworthiness.
